

-> Fitting a straight line (called **Hypothesis**) to the data for prediction

Hypothesis Function

$$f(x) = \theta_0 \cdot x_0 + \theta_1 \cdot x_1 + \theta_2 \cdot x_2 \dots \theta_n \cdot x_n$$

Vectorised Form

$$\theta = \begin{bmatrix} \theta_0 \\ \theta_1 \\ \theta_2 \\ \vdots \\ \theta_n \end{bmatrix} \quad x = \begin{bmatrix} x_0 \\ x_1 \\ x_2 \\ \vdots \\ x_m \end{bmatrix}$$

$$\therefore f(x) = \theta \cdot x$$

Cost Function

-> Used to evaluate the performance of a model.

$$J(\theta_0, \theta_1) = \frac{1}{2m} \sum_{i=1}^m (h_{\theta}(x_i) - y_i)^2$$

Gradient Descent

-> Optimization algorithm that decreases the cost function

How it works

- Checks the value of θ at every step
- If it's lower than the previous value, it edits the value to the new one
- Continues till the deepest point in the slope is reached

Where to use Linear Regression

-> The data should have a linear relationship

-> There should be no/little multicollinearity
